Abstract

We have observed highly virtual ($Q^2 > 1.05 \text{ GeV}^2$) photon-photon collisions to hadronic final states at $\sqrt{s_{e^+e^-}} = 58 \text{ GeV}$. The integrated luminosity of the data sample was 241 pb^{-1} . Both scattered beam-electrons and scattered beam-positrons were detected using low-angle calorimeters (i.e., both photons were highly virtual, “double-tag”); we obtained 115 hadronic events with an estimated background of 10.2 ± 1.1 . The cross section obtained was $4.11 \pm 0.66 \text{ pb}$ in the $2 < W_{\gamma\gamma} < 25 \text{ GeV}$ and $Q_{\gamma, \min}^2 > 2 \text{ GeV}$ region, while the lowest order quark-parton model predicted 3.00 pb .

A measurement of the total hadronic cross section in highly virtual photon-photon collisions ($e^+e^- \rightarrow e^+e^- \text{hadrons}$) is reported for center-of-mass energy, W , between 2 and 25 GeV. In this experiment both the scattered e^+ and e^- , referred as tags, were detected. Such a technique is called “double-tag” [1]. The range of photon four-momentum squared, q^2 , for this experiment was -1.05 to -37 GeV². q^2 's and W were detected on an event-by-event basis directly from the tags. Theoretical calculation of such events in which two large scales of virtuality exist, does not rely on any high P_T selection in the hadronic final state. The measurement thus amounts to a first measurement of a well defined total hadronic cross section in which there could be minimal sensitivity to QCD cut-offs.

Examples of Feynman diagrams which contribute to $\gamma\gamma$ collisions are shown in Figures 1 (a)-(e). Figure 1 (a) is called multi-peripheral or “direct process” which is expected to be dominant in these events [2]. Figures 1 (b), (c), and (d) are examples of a bremsstrahlung, conversion, and annihilation diagram. Figure 1 (e) is an example of “resolved photon process” which is considered to be a smaller contribution in highly virtual photon-photon collisions [3].

The statistics and virtualities of the photons of the experimental data are the highest compared with previous experiments [4].

The integrated luminosity of the event sample is 241pb⁻¹ at $\sqrt{s} = 58 \text{ GeV}$. The details concerning the TOPAZ detector at TRISTAN can be found in reference [5].

To select virtual photon-photon collision events, we used a pair of low-angle calorimeters (FCL) made of Bismuth Germanate crystals (BGO) [6]. This covered the polar-angle region of 3.2 to 12 degrees with respect to the beam axis. The energy resolution was measured to be 5% for Bhabha electrons, and 3% for 4-GeV electron beams. We required that both of the FCL's (electron and positron sides) had single clusters of energies greater than $0.4E_b$ where E_b is the beam energy. This cut was determined in order to reduce contributions from the resolved-photon process [7] and initial (final) state radiation in various processes. It also helped us to reject any background from spent electrons in the accelerator beams. Under these conditions the virtuality of the photon ($Q^2 = -q^2$) was ensured to be greater

than 1.05 GeV².

The trigger system for the TOPAZ detector consisted of neutral and charged-track triggers. The conditions for the neutral triggers were as follows: (a) The total energy deposited in a barrel calorimeter (BCL, made of lead-glass) or an endcap calorimeter (ECL, made of Pb-streamer-tube sandwiches) must be greater than 2 or 4 (63% of the events were taken with a 2-GeV threshold of the BCL, and the others with a 4-GeV threshold.) and 10 GeV, respectively; (b) The BCL was segmented into three parts and the ECL into 4 parts. For energy deposits in these parts, 1 GeV (for BCL) and 4 GeV (for ECL) thresholds were set. Any two hits caused trigger signals. The charged-track trigger required at least two tracks from the origin. The P_T of each track was required to be greater than 0.3~0.7 GeV (run dependent), and the opening angle between one of the pairs must be greater than 45~90 degrees. The cut values depended on the beam conditions; their variation throughout the data taking were taken into account in Monte-Carlo simulations. The details can be found in reference [8].

We used a time-projection-chamber (TPC), the BCL, and the ECL in event selection. Detailed analyses of these detectors can be found in reference [9].

We required at least three charged tracks from the origin with a P_T greater than 0.15 GeV. The invariant mass (W_{VIS}) of the visible particles (in the TPC and BCL) had to be greater than 2 GeV. Here, the energy threshold of the BCL neutral clusters had to be greater than 100 MeV. The visible energy in this region had to be less than 25 GeV.

In order to reduce the backgrounds from annihilation events which were produced at low angle, we required that the energy flow into the ECL be less than that into the BCL.

The material thickness in front of the TPC was ~ 0.3 radiation length. Therefore, we had to pay special attention to $e^+e^- \rightarrow e^+e^-e^+e^-(\gamma)$. Using dE/dx measurements from the TPC we identified electron tracks in the events. To reject this process, we required that an event must contain at least two non-electron tracks.

Finally, we obtained a total of 115 events. We investigated three sources of background: (a) beam-gas and accidental coincidences by spent electrons, (b) $e^+e^- \rightarrow q\bar{q}(n\gamma)$, and (c)

$e^+e^- \rightarrow e^+e^-l^+l^-(n\gamma)$ where l is a lepton.

- (a) Using the Bhabha-scattering events in the central region of the detector, as well as random triggered events, we estimated the background level of the accidental hits in the FCL. The accidental rate was measured to be less than 0.1%. The contamination of the beam-gas scattering was estimated by using off-vertex events in the experimental sample. It was estimated to be 1.0 ± 0.7 events.
- (b) The KORALZ generator was used to simulate the initial (ISR) and final (FSR) state radiation with multiple γ 's [10,11]. Here, the maximum energy (k_{max}) of the radiated photon was set at $0.97E_b$ for b-quark events and $0.99E_b$ for the other quarks. The next-to-leading order (α_s) correction and hadronization was carried out using JETSET 6.3 [11,12]. The contamination of this process was estimated to be 2.3 ± 0.7 events.
- (c) The FERMISV generator was used to simulate this process [13]. This generator could also simulate ISR and FSR. k_{max} was set at $0.8E_b$. The contamination was estimated to be 6.9 ± 0.6 events; τ -pair events dominantly contributed (6.0 ± 0.5 events).

In total, the background contamination in this sample was estimated to be 10.2 ± 1.1 events. We have thus obtained a clean sample of direct photon-photon collision events.

The average of smaller and larger Q^2 's of two photons of this event sample were 5.1 and 12.3 GeV². Both are equally highly virtual. We derived the differential cross sections of $e^+e^- \rightarrow e^+e^-hadrons$ with respect to $W_{\gamma\gamma}$ at several $Q_{\gamma,min}^2$ cuts, where $Q_{\gamma,min}^2$ was a minimum of two Q_γ^2 detected by the forward and backward FCL counters. The cross section such as $\sigma_{\gamma\gamma \rightarrow hadrons}$ or photon structure function would be a future subject in which we need more statistics and works. We used the FERMISV code for deriving the acceptance correction factors with our detector simulation codes. We again set $k_{max} = 0.8E_b$ for ISR and FSR in FERMISV. We restricted events with all four fermions in the final state having polar angles greater than 2.5 degrees from the beam axis. The minimum invariant masses

for hadronic system were set to 2 GeV for light quark events, $2m_D$ for c, and $2m_B$ for b, respectively. The cosines of scattered electrons (positrons) were required to be within $0.9762 < |\cos\theta| < 0.9986$. Quark masses used were 0.35 GeV for u,d, 0.5 GeV for s, 1.35 GeV for c, and 4.5 GeV for b. The hadronization process was simulated using JETSET 6.3 string fragmentation [12,14]. The obtained cross sections are shown in Table I for various kinematic ranges. Also shown are the ratios between the experimental and theoretical cross sections and the T-ratios which are the ratio between $\sigma_{exp}(e^+e^- \rightarrow e^+e^-q\bar{q})/\sigma_{theory}(e^+e^- \rightarrow e^+e^-\mu^+\mu^-)$, where only the multi-peripheral diagram is taken into account in calculating σ_{theory} . Radiative corrections were carried out in deriving these values. The cross section obtained was $4.11 \pm 0.66\text{pb}$ in the $2 < W_{\gamma\gamma} < 25$ GeV and $Q_{\gamma,min}^2 > 2$ GeV region, while the lowest order (LO) theory predicted by FEMISV is 3.00pb. Figure 2 shows the ratios between the experimental and LO-theoretical cross sections. Observed distributions such as W_{VIS} and number of charged tracks were consistent with the Monte-Carlo prediction within statistical errors except for overall normalizations. On the other hand, the experimental data agreed with the theoretical predictions at high Q_γ^2 , including overall normalization factors. The errors shown are both statistical and systematic. We consider the systematic errors below.

The systematic errors were estimated separately concerning the FCL, trigger, and event selection.

- FCL: We changed the energy threshold in the clustering algorithm, as well as that in electron tagging. The dependence of the acceptance was compared with a Monte-Carlo simulation. Also, background contamination was studied by comparing it with Bhabha and random-triggered events. The systematic error due to the FCL was estimated to be 5.2%.
- Trigger: We added noise hits in the tracking detector to the Monte-Carlo simulations. We also studied the acceptance dependence on the energy thresholds of the neutral triggers. The error was estimated to be 6.0% based on the ambiguity in the hardware

settings (10%).

- Event selection: We changed the cut values and derived the cross sections. The differences were taken into account as errors (4.9%).
- Hadronization: We used JETSET 6.3 for hadronization of $q\bar{q}$ system [12]. We changes parameters of string fragmentation a and σ_q in the ranges 0.4-0.7 GeV⁻² and 0.35-0.45 GeV, respectively. The acceptance differences were taken into account as systematic errors. Their bin-to-bin average was 8.9%.

An error of integrated luminosity was estimated to be 4%. The errors except for luminosity and trigger were derived by a bin-by-bin bases. For example a luminosity error is common for all bins, i.e., correlates positively. The correlated systematic error was estimated to be 7.2%. The average bin-by-bin systematic errors was estimated to be 13.5%. The first errors quoted in Table I are statistical and the second ones are systematic. The errors in Figure 2 are quadric sums of these errors.

The accuracy of the FCL energy measurements is important for determining $W_{\gamma\gamma}$. The FCL energy was originally calibrated at 4 GeV using AR electron beams at KEK and at 29 GeV by the Bhabha-scattering electrons. In order to check the other energy region, we studied radiative Bhabha events. We selected acoplanar Bhabha events where the radiated γ direction was consistent with the FCL fiducial volume. The agreement between the BCL-predicted and the FCL-measured energies was as expected from our Monte-Carlo simulation. The Monte-Carlo simulation predicted that the $W_{\gamma\gamma}$ resolution would be almost constant (~ 3 GeV) in the observed energy region ($2 < W_{\gamma\gamma} < 25$ GeV). This was better than the W_{VIS} determined from the TPC and BCL.

In conclusion, we have observed highly virtual ($Q^2 > 1.05$ GeV²) photon-photon collisions to hadronic final states at $\sqrt{s_{e^+e^-}} = 58$ GeV. The integrated luminosity of the data sample was 241 pb⁻¹. The beam electrons (positrons) were tagged by low-angle calorimeters; we obtained 97.3 ± 10.3 events in the $2 < W_{\gamma\gamma} < 25$ GeV and $Q_{\gamma,min}^2 > 2$ GeV region, the Monte-Carlo with LO theory predicted 65.6 ± 2.2 events where the errors are statistical. In

this new kinematic region the contribution of the LO $q\bar{q}$ diagram is expected to dominate. With systematic errors included, the ratio between experimental and theoretical data becomes 1.48 ± 0.26 . The cross sections were measured to be $4.11 \pm 0.66 \text{ pb}$ in the region where $Q^2 > 2 \text{ GeV}^2$ and $2 < W_{\gamma\gamma} < 25 \text{ GeV}$.

We thank Drs. H. Terazawa, M. Kobayashi, K. Hagiwara, and T. Izubuchi for helpful discussions. We also thank the TRISTAN accelerator staff for the successful operation of TRISTAN. The authors appreciate all of the engineers and technicians at KEK as well as those of the collaborating institutions: H. Inoue, N. Kimura, K. Shiino, M. Tanaka, K. Tsukada, N. Ujiie, and H. Yamaoka.
